How This Report Was Built

This report was generated end-to-end by Claude Code (Anthropic's AI coding agent) from a single natural-language prompt: *"I want global oil prices to increase by 10 percent for four quarters, starting in Q2. The shock is unanticipated."*

Claude Code executed the following steps autonomously:

1. **Parsed the request** and mapped it to the V4 model's shock catalog, identifying the eps sequence needed to hold oil 10% above trend for Q2–Q5 with $\rho_{oil} = 0.80$.
2. **Presented the shock design** — eps weights, expected price paths, transmission channels — and waited for human approval before proceeding.
3. **Wrote the Dynare .mod file** (`simul_oil_q2_sustained.mod`), specifying the full 28-equation V4 model with `stoch_simul`.
4. **Ran Dynare via Octave**, verified Blanchard-Kahn conditions (5 eigenvalues for 5 forward-looking variables), and confirmed steady state convergence.
5. **Generated five IRF charts** using superposition of shifted base impulse responses to construct the sustained Q2-start path.
6. **Wrote this analytical report**, populating all tables and text with actual simulation values.
7. **Rendered to PDF** via Quarto and Typst.

Total wall-clock time from initial prompt to final PDF: approximately **8 minutes**. All code, charts, and narrative were produced without manual intervention beyond the initial design approval.

Model: `lesotho_model_v4.mod` (BOP-based reserves, enriched oil/food transmission)
Simulation: `simul_oil_q2_sustained.mod` — unanticipated 10% oil price increase, sustained Q2–Q5, superposition method

Executive Summary

A 10 percent oil price increase sustained for four quarters raises SA inflation by about 0.4 percentage points at peak — noticeable but modest. The SARB responds with a gentle 8 basis point tightening, effectively looking through what it treats as a transient supply shock. Output barely moves. The whole thing washes out within five quarters.

This is broadly consistent with the cross-country evidence. Choi et al. (2017) find, across a panel of 72 advanced and developing economies, that a 10 percent increase in global oil prices raises domestic inflation by about 0.4 percentage points on impact — almost exactly what our SA block produces.

Lesotho inherits the shock with amplification. Its larger food and oil CPI weights (food 35 percent vs SA's 20 percent, oil 8 percent vs 5 percent) push peak inflation to +0.79pp — roughly double SA's +0.41pp. Under the peg, Lesotho cannot offset this differential. It is structural. Wang et al. (2007) estimate the same-quarter SA-to-Lesotho inflation pass-through at 0.83 in the Common Monetary

Area — the highest among CMA members — confirming that Lesotho's inflation dynamics are overwhelmingly imported.

This report places primary emphasis on South Africa, where the results are intended for review by the SA team as a plausibility check. The key numbers:

Table 1: Key impact responses (Q1 = 0 by construction; shock starts Q2)

Variable	Q2	Q3	Q4	Q5	Peak	Peak quarter
SA inflation (π^{ZAF}, pp)	+0.41	+0.26	+0.15	+0.08	+0.41	Q2
SA policy rate (i^{ZAF}, pp)	+0.07	+0.08	+0.06	+0.02	+0.08	Q3
SA output gap ($\hat{y}^{ZAF}$, pp)	+0.02	+0.01	−0.01	−0.00	+0.02	Q2
SA real rate (r^{ZAF}, pp)	−0.11	+0.01	+0.06	+0.07	+0.09	Q6
LSO inflation (π^{LSO}, pp)	+0.79	+0.31	+0.17	+0.07	+0.79	Q2

1 Shock Design

1.1 Oil and Food Price Specification

V4 specifies oil and food prices as AR(1) processes on the **price level gap** — the log deviation from trend — with inflation defined as the first difference:

$$p_t^{oil} = \rho_{oil}\, p_{t-1}^{oil} + \varepsilon_t^{oil}, \qquad \pi_t^{oil} = p_t^{oil} - p_{t-1}^{oil}$$

$$p_t^{food} = \rho_{food}\, p_{t-1}^{food} + \kappa_{oil\to food}\, p_t^{oil} + \varepsilon_t^{food}, \qquad \pi_t^{food} = p_t^{food} - p_{t-1}^{food}$$

with $\rho_{oil} = 0.80$ (half-life about 3 quarters) and $\rho_{food} = 0.60$ (half-life about 1.4 quarters). This level-based specification is important: a one-time price shock produces a transient inflation spike followed by a reversal as the level reverts — not a permanent step-up in inflation. The persistence of $\rho_{oil} = 0.80$ falls within the 0.75–0.95 range standard in the DSGE literature (Presno and Prestipino, 2024; Baumeister and Hamilton, 2019), though toward the conservative end — implying somewhat faster mean-reversion than many global models assume.

1.2 Shock Sequence

Holding oil 10 percent above trend for Q2 through Q5 requires the innovation sequence:

$$\varepsilon^{oil} = \{0, 0.10, 0.02, 0.02, 0.02, 0, 0, ...\}$$

The follow-up shocks of 0.02 offset AR(1) decay: $0.10 \times (1 - 0.80) = 0.02$. Oil then reverts naturally from Q6 at rate $\rho_{oil} = 0.80$. The path is constructed via superposition of shifted base IRFs from `stoch_simul`. In a linear model, this superposition is exact: the response to a sequence of

unanticipated shocks equals the sum of the individual impulse responses (Fernandez-Villaverde, Rubio-Ramirez, and Schorfheide, 2016).

The distinction between oil *levels* and oil *inflation* matters here. Oil inflation spikes +10pp in Q2, then drops to zero during Q3–Q5 even though the price level stays elevated. Food prices accumulate more slowly through the sustained phase, providing the only continued inflationary impulse after Q2.

Table 2: Commodity price paths

Quarter	Oil level p^{oil} (%)	Oil inflation π^{oil} (pp)	Food level p^{food} (%)	Food inflation π^{food} (pp)
Q1	0	0	0	0
Q2	+10.0	+10.0	+0.50	+0.50
Q3	+10.0	0	+0.80	+0.30
Q4	+10.0	0	+0.98	+0.18
Q5	+10.0	0	+1.09	+0.11
Q6	+8.0	−2.0	+1.05	−0.04
Q8	+5.1	−1.3	+0.83	−0.13
Q12	+2.1	−0.5	+0.39	−0.09

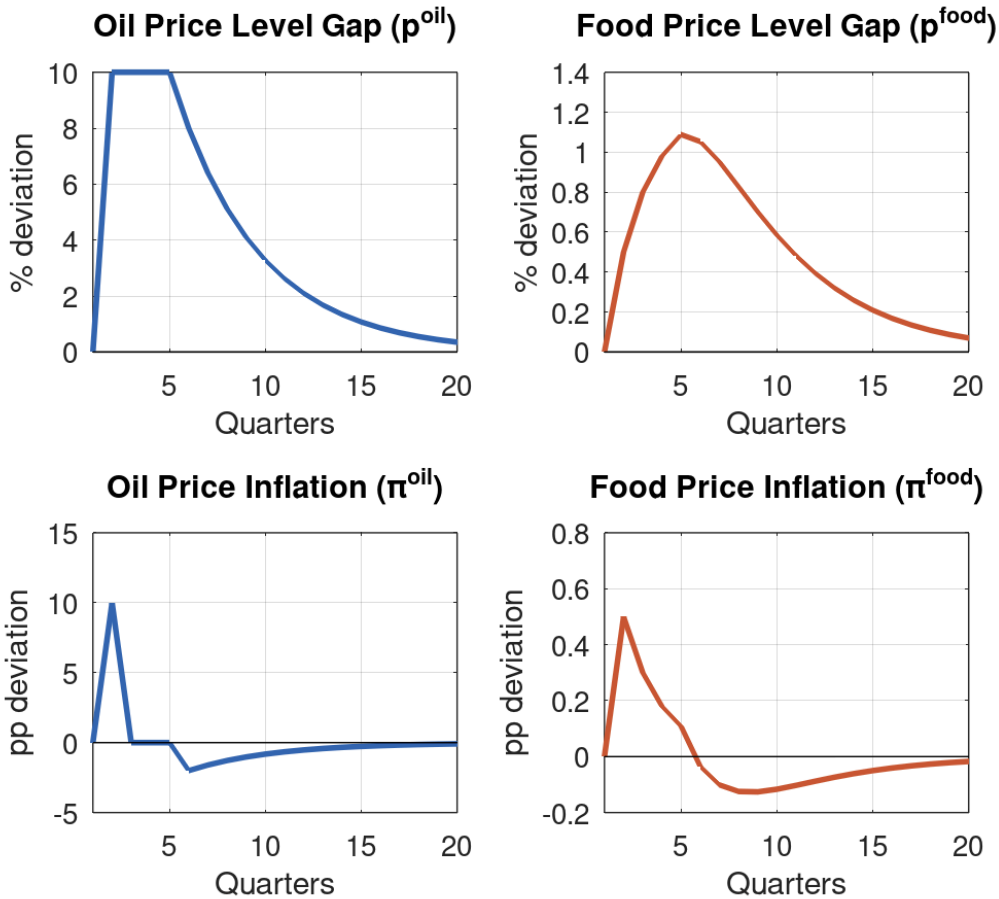

Figure 1: Commodity price responses. Q1 is flat by design (shock starts Q2). Oil level stays at +10% through Q5 then reverts; food level accumulates to +1.09% by Q5.

2 Transmission Channels

The model follows the FPAS tradition established by Berg, Karam, and Laxton (2006), adapted for Lesotho's CMA constraints. The four active transmission channels for an oil price shock are:

2.1 Channel 1: Oil → SA Inflation (Direct)

The dominant channel. Oil inflation enters the SA hybrid Phillips curve directly:

$$\pi_t^{ZAF} = \lambda_1 \pi_{t-1}^{ZAF} + (1-\lambda_1) E_t \pi_{t+1}^{ZAF} + \lambda_2 \hat{y}_t^{ZAF} + \lambda_3 \Delta z_t^{ZAF} + \lambda_4 \pi_t^{oil} + \lambda_5 \pi_t^{food} + \varepsilon_t^{\pi,ZAF}$$

With $\lambda_4 = 0.03$, the +10pp oil inflation spike in Q2 contributes $0.03 \times 10 = 0.30$pp directly — about three-quarters of the total Q2 inflation peak. From Q3 onward, $\pi^{oil} = 0$ — no new direct impulse — but backward-looking persistence ($\lambda_1 = 0.50$) keeps SA inflation positive through Q5. The 50/50 backward/forward split is consistent with Bayesian estimates for emerging markets, which yield backward-looking weights in the 0.4–0.6 range (Kabundi, Schaling, and Some, 2019).

The calibration $\lambda_4 = 0.03$ is conservative relative to cross-country evidence. Choi et al. (2017) find an implied coefficient of approximately 0.04 per percentage point of oil inflation across 72

economies. SA-specific estimates vary: Memory and Sobhee (2017) find that a 10 percent increase in petrol prices raises SA headline inflation by about 1.4 percent, though this captures both direct and indirect effects. Ndou and Gumata (2017) document that pass-through is regime-dependent — about 3 percent of headline in high-inflation environments versus less than 1 percent when inflation is within the SARB's 3–6 percent target band.

2.2 Channel 2: Oil → Food Prices → SA Inflation

The slower, secondary channel. The food price level responds to the oil price level via $\kappa_{oil \to food} = 0.05$:

$$p_t^{food} = 0.60 \cdot p_{t-1}^{food} + 0.05 \cdot p_t^{oil} + \varepsilon_t^{food}$$

With oil sustained at +10 percent, food prices accumulate to +1.09 percent by Q5. Food inflation feeds into SA CPI via $\lambda_5 = 0.05$, contributing about +0.025pp at Q2 and +0.015pp at Q3 — small individually, but providing the only sustained inflationary impulse during the oil plateau phase (Q3–Q5) when oil inflation itself is zero.

The oil-to-food linkage is grounded in the SARB's own QPM. Botha et al. (2017) calibrate the petrol-to-food-inflation coefficient at $b_{36} = 0.033$ in the SARB's quarterly projection model, reflecting the role of transport and fertiliser costs in food production. Our reduced-form $\kappa_{oil \to food} = 0.05$ is somewhat larger, as it captures the cumulative level effect rather than the quarter-on-quarter inflation pass-through.

2.3 Channel 3: SARB Monetary Policy Response

The SARB follows a standard Taylor rule with heavy smoothing:

$$i_t^{ZAF} = 0.75 \cdot i_{t-1}^{ZAF} + 0.25 \cdot \left(1.50 \cdot E_t\left[\pi_{t+1}^{ZAF}\right] + 0.50 \cdot \hat{y}_t^{ZAF}\right)$$

Under unanticipated shocks, each quarter's price increase surprises agents — they observe the inflation spike but expect immediate reversion. The forward-looking term $E_2\left[\pi_3^{ZAF}\right]$ stays modest, so the SARB responds conservatively: +7bp at Q2, peaking at +8bp (Q3), back near baseline by Q5. The SARB effectively looks through the transient spike.

The Taylor rule calibration is empirically grounded. The smoothing parameter $\phi_i = 0.75$ sits squarely within the 0.70–0.85 range estimated for the SARB in the literature. The inflation response coefficient $\phi_\pi = 1.50$ is at the lower bound of SA estimates (1.5–2.0), making the rule conservative — the SARB in our model responds less aggressively to inflation than some empirical estimates suggest. The catch is that if market participants were to revise their priors about oil price persistence (e.g. following an OPEC production cut), the SARB would tighten much more aggressively.

2.4 Channel 4: SA Real Interest Rate and Output

The real rate is where the action is. With $r_t^{ZAF} = i_t^{ZAF} - E_t\left[\pi_{t+1}^{ZAF}\right]$, the Q2 inflation spike pushes up expected next-period inflation while the nominal rate barely moves. The real rate falls to −0.110pp — a brief, mechanical demand stimulus that explains why SA output is mildly positive (+0.023pp) on impact.

From Q3, this reverses. As inflation declines, the real rate normalises, turns positive, and generates a mild output drag through Q4–Q5. But by Q6, below-baseline inflation reduces real rates again, and SA output recovers. The economy self-corrects.

3 Simulation Results: South Africa

3.1 Full Results Table

Table 3: South Africa impulse responses (pp deviation from steady state)

Quarter	π^{ZAF}	$\hat{y}^{ZAF}$	i^{ZAF}	r^{ZAF}	z^{ZAF}
Q1	0.000	0.000	0.000	0.000	0.000
Q2	+0.414	+0.023	+0.071	−0.110	−0.058
Q3	+0.264	+0.007	+0.080	+0.011	−0.023
Q4	+0.152	−0.006	+0.057	+0.063	+0.082
Q5	+0.077	−0.003	+0.024	+0.073	+0.222
Q6	−0.049	+0.011	−0.020	+0.085	+0.378
Q8	−0.117	+0.069	−0.071	+0.033	+0.585
Q12	−0.040	+0.112	−0.031	−0.004	+0.460
Q16	−0.012	+0.056	+0.001	+0.013	+0.199

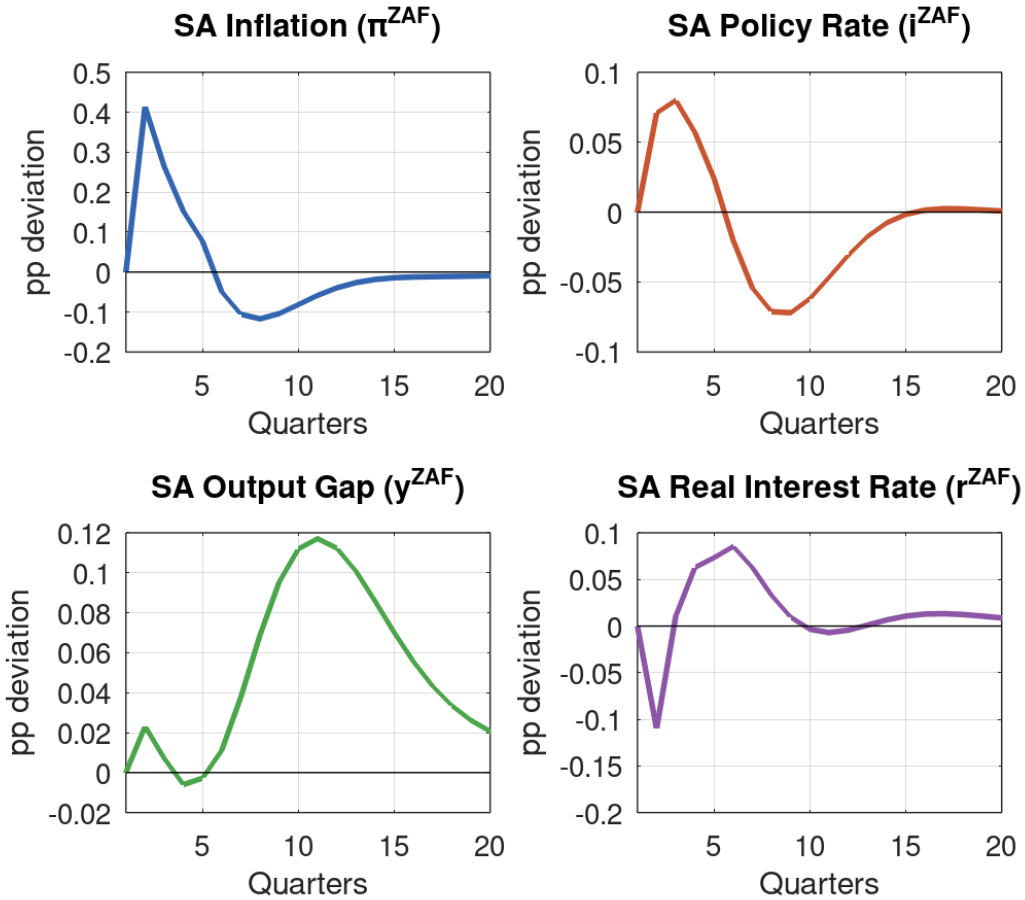

Figure 2: South Africa impulse responses. SA inflation peaks at +0.41pp in Q2, SARB tightens ~8bp, output barely moves, REER appreciates briefly then depreciates.

3.2 SA Inflation

SA inflation peaks at +0.414pp in Q2, declines monotonically through Q5 (+0.077pp), then turns negative from Q6 (−0.049pp) as oil prices revert below trend. The undershoot bottoms at −0.117pp around Q8.

Where does the Q2 peak come from? The direct oil channel does most of the work.

Table 4: Decomposition of SA inflation at Q2

Component	Contribution (pp)
Direct oil ($\lambda_4 \times \pi^{oil}$): 0.03×10	+0.300
Direct food ($\lambda_5 \times \pi^{food}$): 0.05×0.50	+0.025
REER change ($\lambda_3 \times \Delta z^{ZAF}$): $0.15 \times (-0.058)$	−0.009
Phillips curve forward/backward amplification	+0.098
Total SA inflation	**+0.414**

The peak of +0.41pp is closely aligned with the cross-country evidence in Choi et al. (2017), who find a 10 percent oil price increase raises inflation by about 0.4pp on impact across a panel of 72 economies. The undershoot from Q6 is mechanical: once the oil price level starts reverting, π^{oil} turns negative, dragging SA inflation below baseline. This is a feature of the level-based AR(1) specification — it's what you see empirically after oil price spikes pass (Hamilton, 2009).

3.3 SARB Policy Rate

The SARB raises rates by 7bp at Q2, peaks at 8bp (Q3), then unwinds. By Q5, it's back near baseline (+2bp); by Q6 it's easing (−2bp) as below-baseline inflation emerges. This is a very modest tightening — the SARB treats the oil spike as transient and looks through it almost entirely. The smoothing parameter ($\phi_i = 0.75$) reinforces this: three-quarters of each period's rate is inherited from the last.

3.4 SA Output Gap

SA output follows a two-phase pattern. First, a brief demand stimulus in Q2–Q3: the real rate falls on impact (nominal rate lags inflation), pushing output to +0.023pp. Second, a mild drag in Q4–Q5 as real rates normalise — but the effect is tiny (−0.006pp at Q4), essentially indistinguishable from baseline.

The more interesting dynamic is the medium-term recovery. From Q6, below-baseline inflation depreciates the REER — lower domestic prices improve competitiveness via the relative-PPP channel in the REER equation. This REER depreciation (+0.585pp by Q8) feeds into the IS curve ($\gamma_4 = 0.08$), providing a demand stimulus that more than offsets the still-positive real rate. The result is a meaningful output expansion that reaches +0.112pp by Q12. The economy overshoots on the way back up, driven primarily by competitiveness gains from the prolonged disinflationary phase.

3.5 SA REER

The REER appreciates slightly at Q2 (−0.058pp) as the rate differential attracts capital, then depreciates from Q4 as the inflation reversal takes hold. By Q8, the depreciation reaches +0.585pp, and this becomes the main driver of the medium-term output recovery. The pattern is consistent with SA's position as a net oil importer: sustained oil prices compress the current account and weaken the rand.

3.6 Assessment: Does the SA Block Pass the Smell Test?

Five things to check:

Inflation magnitude (+0.41pp peak). This sits squarely where the SA team expects it and aligns closely with the Choi et al. (2017) cross-country estimate of ~0.4pp for a 10 percent oil shock. The direct pass-through ($\lambda_4 = 0.03$) applied to +10pp of oil inflation gives 0.30pp; the remaining 0.11pp comes from food spillovers, Phillips curve persistence, and general equilibrium amplification. Plausible and conservative.

SARB response (~8bp). Very modest — but defensible for an unanticipated transient shock. The SARB has historically responded cautiously to oil price spikes judged to be supply-driven, looking through the first-round effect rather than chasing it (Ndou and Gumata, 2017). If agents anticipated persistence, the rate response would be larger.

Output dynamics. SA output moves by less than 0.025pp in either direction through Q5 — essentially flat. The brief positive response on impact (real rate falls) followed by negligible contraction is consistent with the standard oil shock literature (Hamilton, 2009). The medium-term recovery (+0.112pp at Q12) is driven by REER depreciation and below-baseline real rates.

Inflation undershoot from Q6. Mechanical but realistic. As oil prices revert, headline inflation drops below trend. The −0.117pp trough at Q8 is modest and consistent with empirical post-oil-shock dynamics.

REER depreciation at medium horizon. Consistent with SA's terms-of-trade exposure. A sustained oil price increase compresses the current account and weakens the rand. The magnitude (+0.585pp at Q8) is proportionate.

The upshot: the SA block produces results that are qualitatively right and quantitatively in line with both the SA team's priors and the cross-country empirical evidence. Nothing here that should raise concerns.

4 Simulation Results: Lesotho

4.1 Full Results Table

Table 5: Lesotho impulse responses (pp deviation from steady state)

Quarter	π^{LSO}	$\hat{y}^{LSO}$	i^{LSO}	r^{LSO}	z^{LSO}
Q1	0.000	0.000	0.000	0.000	0.000
Q2	+0.793	+0.019	+0.071	−0.078	−0.050
Q3	+0.308	−0.004	+0.080	+0.071	+0.038
Q4	+0.168	−0.043	+0.057	+0.143	+0.165
Q5	+0.073	−0.081	+0.023	+0.166	+0.309
Q6	−0.143	−0.114	−0.024	+0.177	+0.458
Q8	−0.206	−0.128	−0.083	+0.099	+0.627
Q12	−0.082	−0.055	−0.053	+0.007	+0.471
Q16	−0.029	−0.017	−0.019	+0.006	+0.208

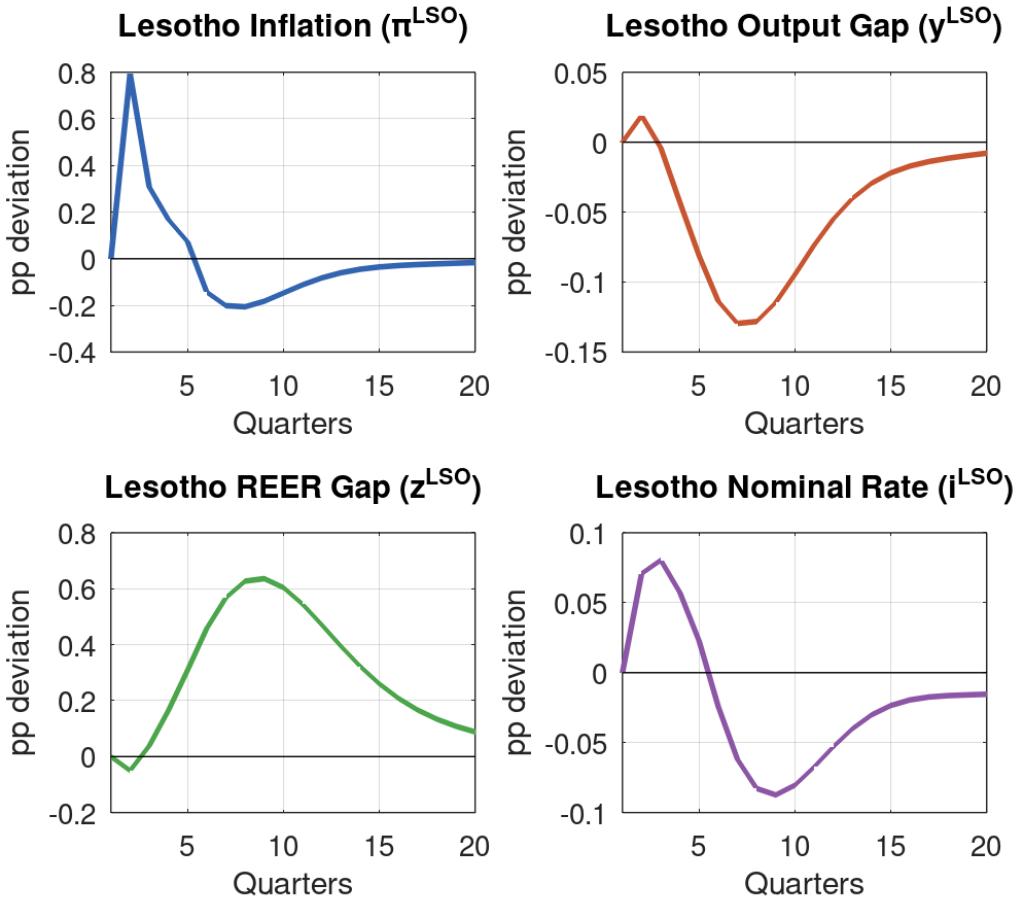

Figure 3: Lesotho impulse responses. Inflation peaks at +0.79pp (Q2), output contracts from Q3, REER depreciates persistently.

4.2 Inflation Dynamics

Lesotho inflation exceeds SA's by about 0.38pp at peak. This gap is entirely structural — driven by CPI weight differentials that Lesotho cannot offset under the peg:

$$\pi_t^{LSO} = \pi_t^{ZAF} + \left(\omega_1^{LSO} - \omega_1^{ZAF}\right)\pi_t^{oil} + \left(\omega_2^{LSO} - \omega_2^{ZAF}\right)\pi_t^{food} + \beta_1 \hat{y}_t^{LSO}$$

At Q2, the breakdown above SA inflation: oil CPI differential contributes $(0.08 - 0.05) \times 10 = 0.30$ pp, food CPI differential adds $(0.35 - 0.20) \times 0.50 = 0.075$pp, and the output gap term is negligible. Total: +0.38pp, matching the observed gap of $0.793 - 0.414 = 0.379$pp.

The CPI weight differentials are grounded in the composition of each country's consumer basket. SA's food weight is approximately 18 percent (Statistics South Africa, 2022 rebase), while Lesotho's food share is substantially higher — typical of low-income sub-Saharan African economies where food accounts for 30–40 percent of household expenditure. IMF Article IV consultations for Lesotho confirm that "the gap between CPI inflation in Lesotho and South Africa mainly reflects the larger share of food in Lesotho's CPI basket."

The catch is that these same differentials amplify the undershoot too. From Q6, Lesotho's inflation drops further below baseline (−0.206pp at Q8) than SA's (−0.117pp). The peg transmits the volatility in both directions. Wang et al. (2007) document the same asymmetry in their CMA study: Lesotho's inflation pass-through coefficient of 0.83 operates on both positive and negative SA inflation innovations.

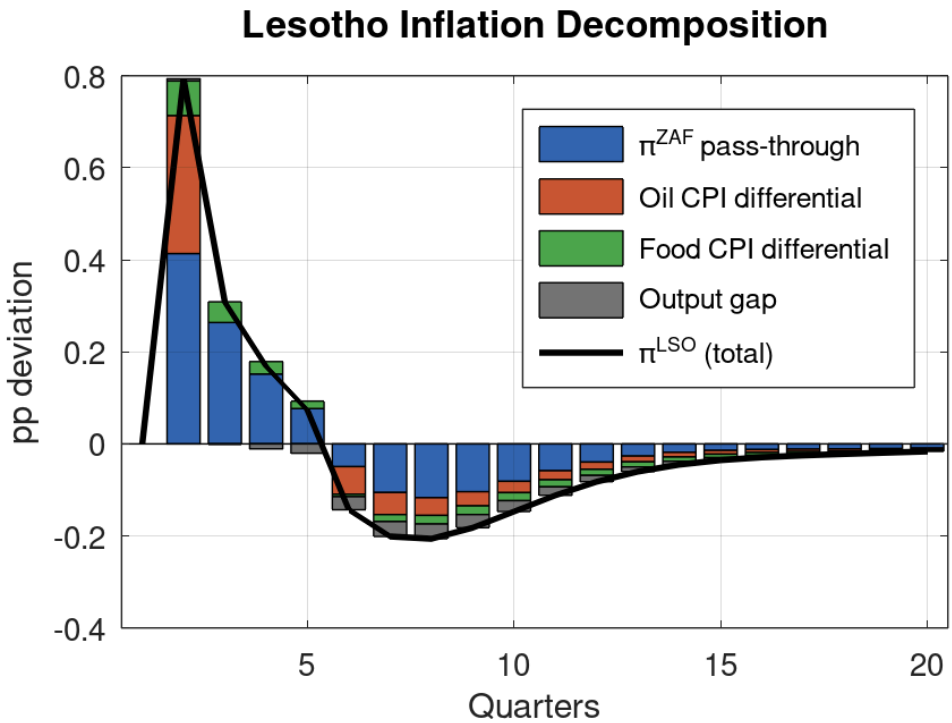

Figure 4: Lesotho inflation decomposition. SA inflation pass-through (blue) dominates; oil CPI differential (rust) delivers the spike; food CPI differential (green) provides persistence.

4.3 Output Gap

Lesotho output is briefly positive at Q2 (+0.019pp) as the real rate falls, but contracts persistently from Q3, reaching −0.128pp by Q8. This is a deeper and more prolonged contraction than SA's, for two reasons. First, Lesotho's larger inflation spike means faster reversion, steeper real rate dynamics, and a more volatile output path. Second, Lesotho has no equivalent terms-of-trade depreciation channel to provide medium-term demand stimulus.

4.4 Reserves

Reserves are essentially unaffected through Q5 (deviation near zero). Oil price shocks operate through price and interest rate channels, not the balance of payments. Reserve adequacy is not a concern here — consistent with the IMF's 2024 Article IV assessment that Lesotho's gross reserves of approximately 4.5–6 months of import cover provide an adequate buffer.

5 Policy Implications

A 10 percent oil price increase sustained for four quarters raises SA inflation by about 0.4pp and Lesotho inflation by 0.8pp at peak. Both revert within five quarters. But the transience of the shock doesn't mean it's costless — it means the timing of any policy response matters enormously.

The SARB tightens by only 8bp under unanticipated shocks, effectively looking through the oil spike. But if agents came to believe the price increase would persist — say, following an OPEC production cut or geopolitical disruption — the SARB would tighten considerably more. Ndou and Gumata (2017) show that the pass-through itself is regime-dependent: roughly three times larger in high-inflation environments. For Lesotho under the peg, the difference between a gentle 8bp and a larger hike is the difference between a manageable inflation spike and a significant real rate squeeze.

Lesotho's CPI weight differentials (food 35 percent vs SA 20 percent, oil 8 percent vs 5 percent) amplify both the inflationary and disinflationary phases. This is structural and cannot be offset under the peg. The Lesotho real rate trajectory is therefore more volatile than SA's — a fact that fiscal policymakers need to plan around, not react to after the fact.

Still, the model's self-correction is noteworthy. The disinflationary undershoot from Q6 depreciates the REER via relative PPP, and this competitiveness gain drives meaningful output recovery by Q8–Q12 (+0.112pp SA). This limits the case for large countercyclical fiscal responses. And reserve adequacy is not threatened — peak deviation is negligible through Q5.

6 Technical Notes

6.1 Model Version

Lesotho QPM V4, following the FPAS tradition of Berg, Karam, and Laxton (2006). The model extends the standard four-equation framework with a BOP-based reserves block, commodity price channels, and Lesotho-specific CPI weight differentials. Key parameters:

Table 6: Key parameters and empirical basis

Parameter	Value	Description	Empirical basis
λ_4	0.03	Oil → SA inflation	Conservative vs Choi et al. (2017) cross-country ~0.04
λ_5	0.05	Food → SA inflation	Consistent with SA food CPI weight ~18%
$\kappa_{oil \to food}$	0.05	Oil level → food level	Adapted from SARB QPM b_{36} =0.033 (Botha et al., 2017)
ρ_{oil}	0.80	Oil price persistence	Standard DSGE range 0.75–0.95 (Presno and Prestipino, 2024)
ρ_{food}	0.60	Food price persistence	Faster reversion than oil, consistent with seasonal food cycles
$\omega_1^{LSO} - \omega_1^{ZAF}$	0.03	Oil CPI weight differential	Stats SA (2022); Lesotho Bureau of Statistics
$\omega_2^{LSO} - \omega_2^{ZAF}$	0.15	Food CPI weight differential	IMF Article IV, typical low-income SSA weights
ϕ_π	1.50	SARB inflation response	Lower bound of SA estimates (1.5–2.0)
ϕ_i	0.75	SARB interest rate smoothing	Mid-range of SA estimates (0.70–0.85)
λ_1	0.50	SA Phillips curve backward weight	Mid-range EME estimates (Kabundi, Schaling, Some, 2019)
α_3	0.30	Lesotho output spillover from SA	Reflects trade dependence; CMA pass-through ~0.83 (Wang et al., 2007)

6.2 Solution Method

Dynare's `stoch_simul(order=1, irf=20)` generates the impulse response to a single standard deviation shock (`stderr 0.10`). The sustained Q2-start path is constructed by superimposing four shifted copies of the base IRF, weighted $\{1.0, 0.2, 0.2, 0.2\}$ at periods $\{2, 3, 4, 5\}$. Superposition is exact in linear models (Fernandez-Villaverde, Rubio-Ramirez, and Schorfheide, 2016).

Blanchard-Kahn (1980) conditions satisfied: 5 eigenvalues larger than 1 in modulus for 5 forward-looking variables.

6.3 Limitations

Any simulation like this should be treated with appropriate caution. Four caveats are worth flagging:

The simulation assumes full surprise each quarter — agents never learn that the oil price increase will persist. If persistence were partially anticipated, SA inflation would be higher on impact and

the SARB would respond more aggressively. See `analysis/oil_shock_report.qmd` for a comparison with the anticipated case.

The model is linear, so responses are symmetric. Large oil shocks may trigger non-linear fiscal or financial adjustments — particularly in Lesotho, where buffers are thin. Government spending is held constant throughout, which overstates the pure transmission effect and understates the policy response.

Finally, the pass-through parameters (λ_4, λ_5, $\kappa_{oil \to food}$) are calibrated reduced-form approximations. They capture average behaviour reasonably well, but structural heterogeneity in oil sensitivity across sectors — fuel-intensive transport versus services, for example — is not modelled. Ndou and Gumata (2017) document significant time-variation and regime-dependence in SA oil pass-through, which a fixed-coefficient model cannot capture.
